Key words: relationship, feet, spine, pelvis

#### Summary

**Introduction**. The evolution of information technology has resulted in development of normative ranges with regard to the parameters of human body posture which led to further research of their mutual impact, relationships and concomitance.

**Material and method**. The study conducted with the group of children aged 4 to 6 years enabled to record 2988 observations with regard to the measurement of the 90 parameters describing trunk and feet. The station for an assessment of body posture and feet using the photogrammetric method consisted of a computer, a card, software, a display monitor, a printer and a projection-reception device with a camera to measure selected parameters.

#### Findings

1. The values of left foot parameters correlated significantly more with trunk parameters than right foot parameters. Particularly high correlations were observed in the following parameters: length of the fifth arch, surface of plantokonturogram (the plantar side of the feet) and height of the fifth arch, valgity angle of the fifth toe, and heel angle of left foot.

2. Foot parameters revealed the most frequent significant relationship with trunk parameters in the sagittal and frontal planes. Trunk parameters with which foot parameters correlated most often included: asymmetry in the height of both scapulas with the right scapula up, inclination of thoracolumbar region and asymmetry in the height of waist triangles with the right triangle up.

## 1. Introduction

The evolution of information technology has resulted in development of normative ranges with regard to the parameters of human body posture which led to further research of their mutual impact, relationships and concomitance. This issue has been dealt with by Łubkowska [1] and Mrozkowiak [2]. The study carried out by Plaskiewicz et al. using the mora projection method in the group of forty children aged 9-10 years from rural and urban environments in terms of incidence of foot defects revealed that most children from towns (65%) and villages (75%) had correctly shaped feet. Flat feet were reported to be the most common foot defect among the children involved in the study. No significant statistical differences were observed in the assessment of feet between children from rural and urban settlements [3]. The research conducted by Puzder et al. in the group of 92 children aged 9-10 years from both settlements showed that the living environment did not have significant impact on the incidence of static disorders in lower limbs. However, a decreasing tendency was observed in the frequency of examined defects in lower limbs as the time of physical recreation extended. Additionally, a positive correlation was observed between BMI and the incidence of valgus knees and flatvalgus feet [4]. The study performed by Wojnar et al. in the group of 348 children aged 6-7 years revealed a significant percentage of postural defects. More defected body postures in the sagittal plane were reported in 6-year-old subjects whereas in the frontal plane in children aged 7 years. The shape and size of anteroposterior spinal curves and values of the measured

asymmetry indices did not significantly differentiate boys and girls [5]. The research carried out by Walaszek et al. among 60 children at the age of 5 with regard to the longitudinal arch in feet revealed that girls' right feet had deeper arch than their left feet. Moreover, the authors found out that differences in Clarke's indicator between girls' and boys' left feet were statistically insignificant while girls' right feet statistically varied from right feet of boys [6]. The static and dynamic correlations between the parameters of feet and trunk have been discussed in relatively few publications so far. This problem has been explored by Mięsowicz [7-8], Drzał-Grabiec, Snela [9], Mrozkowiak, Sokołowski, and Jazdończyk [10, 11].

The purpose of the study was to determine the concomitance of significant relationships between selected parameters of feet and trunk in the group of 4, 5, and 6-year-olds of both genders and from rural and urban settlements.

The analysis of the study results headed in two directions. The first one was to provide an answer to the question: which parameters of feet most frequently revealed significant relationships with the parameters of trunk? The second one was to give an answer to the question: which parameters of trunk most often correlated with the parameters of feet?

# 2. Material and method

The study conducted with the group of children aged 4 to 6 years enabled to record 2,988 observations. The statistical analysis included 90 angular and linear parameters of the spine, pelvis, trunk and feet in the sagittal, frontal and transverse planes, in particular age, gender and environmental ranges, Table 1. The station for an assessment of body posture and feet using the photogrammetric method consisted of a computer, a card, software, a display monitor, a printer and a projection-reception device with a camera to measure elected parameters. Due to the article constraints, the detailed description of the somatic features of the research material and the obtained results are available in the author's monography [2]. The empirical data were the quantitative and qualitative characteristics (gender, domicile, etc.). The conducted calculations covering the values of position statistics (arithmetic mean, quartiles), the dispersion parameter (standard deviation) and symmetry indicators (asymmetry and concentration indicators) provided a comprehensive view of the distribution of the studied features considering age ranges, gender and environment. The correlations and their significance were assessed using p-value and frequency expressed in percentage.

The fundamental assumption of the study was to assess the habitual posture as a relatively constant individual characteristic of a human being. This posture reflected an individual emotional, psychical and social condition of the subject. Moreover, the posture provided the most reliable description of the subject's silhouette at a given time and in a place. Objectified

and comparable test results ensured that the postural parameters adopted for the analysis were recorded with possible to determine compensations. The combined assessment of the trunk and feet allowed to objectively determine the quality of the postural model applied in a given environment, gender and age category and the degree of correction achieved by physical exercise. The station for an assessment of selected features body posture and feet using the photogrammetric method consisted of a computer, a card, software, a display monitor, a printer and a projection-reception device with a camera to measure selected parameters of the pelvis - spine complex and feet. Obtaining the spatial picture was possible thanks to displaying the line of strictly defined parameters on a teenager's back and feet. The lines falling on the skin of a child got distorted depending on the configuration of the surface. The applied lens ensured that the imaging of a subject could be received by a special optical system with a camera, then transmitted to the computer monitor. The distortions of the line imaging recorded in the computer memory were processed through a numerical algorithm on the topographic map of the investigated surface. When conducting the study, one should be aware of the fact that the taken photo records an image of the silhouette displayed on a child's back. An uneven distribution of subcutaneous adipose tissue along the back makes it difficult to reliably assess body posture in children, especially those with BMI 25 - 30 and over. It is considerably more difficult to determine selected anthropometric measurements in such subjects.

The strongest correlations between foot parameters and trunk parameters, that is over 10%, were observed in the following parameters: length of the fifth arch (19.04%), surface of the plantar side of the feet - plantokonturogram (16.66%), height of the fifth arch (14.28%), valgity angle of the fifth toe (11.9%), and heel angle of left foot (11%).

The parameters like height of the first, second, and fourth arch and length of the fourth arch and length of left foot, width of the fourth and fifth arch in the left foot, height of the third arch and length of the fourth arch in right foot revealed a 9.52% relationship. The remaining parameters were below this threshold, Table 2, Fig. 1.

Further analysis of the study results showed that parameters of feet most significantly, over 20%, correlated with the angle of body bent to the left in the frontal plane (63.01%) and height of lumbar lordosis (52.15%), inclination of upper thoracic region (41.29%), and length of lumbar lordosis (39.11%). Significant correlations with the height of thoracic kyphosis and asymmetry in the height of scapulas with the right one up achieved the level of 32.59%. Moreover, foot parameters were reported to significantly correlate with length of thoracic kyphosis (13.04%), inclination of lumbosacral region (10.86%) and asymmetry in the distance between lower angles of scapulas from spinous process with the lower left angle of scapula being more distant. The parameters of feet correlated with the remaining trunk parameters on the level below 10%, Table 3, Fig. 2.

## 5. Findings

1. The values of left foot parameters correlated significantly more with trunk parameters than right foot parameters. Particularly high correlations were observed in the following parameters: length of the fifth arch, surface of plantokonturogram (the plantar side of the feet) and height of the fifth arch, valgity angle of the fifth toe, and heel angle of left foot.

2. Foot parameters revealed the most frequent significant relationship with trunk parameters in the sagittal and frontal planes. Trunk parameters with which foot parameters correlated most often included: asymmetry in the height of both scapulas with the right scapula up, inclination of thoracolumbar region and asymmetry in the height of waist triangles with the right triangle up.
