Keywords: Neuromuscular training; injury care; sports rehabilitation; meta-analysis

Abstract

Objective: Neuromuscular training is a relatively new comprehensive rehabilitation treatment method in recent years. Although its preventive effect on adolescent sports injuries is indisputable, its specific effects on gender, injury site, and type are still poorly understood. This study evaluated the clinical efficacy of neuromuscular training on adolescents of different genders, injury sites, and types through systematic meta-analysis.

Method: A comprehensive search was conducted on clinical randomized controlled trials related to the prevention of adolescent sports injuries through neuromuscular training in databases such as PubMed, Web of Science, EBSCO, and Scopus. The databases were established until May 2024. The neuromuscular training group (experimental group) used neuromuscular training or neuromuscular training as the main intervention method; The control group is either a blank group or a routine exercise group, without paying special attention to neuromuscular control. Outcome measures include any form of muscle, ligament, or bone injury, including acute or chronic injury data. The quality of the included literature was determined using the Cochrane bias risk assessment tool and the physical therapy evidence database scale, and statistical analysis was conducted using RevMan 5.4 and Stata 16.0 software.This study is registered with the International Platform of Registered Systematic Review and Meta-analysis Protocols (INPLASY), INPLASY2024110054.

Result: A total of 32 clinical randomized controlled trials were included, with a sample size of 34581 cases. The meta-analysis results showed that: 1. The overall effect of neuromuscular training: the experimental group was better than the control group, with a combined IRR of 0.67 (95% CI2 0.57-0.79); Z = 4.78; P < 0.00001). The male group had a higher risk of loss compared to females in the experiment; 2. Upper limb motor injury: combined IRR of 0.73

(95% CI2 0.59-0.9); Z = 3.12; P =0.002). The male group had a lower risk of injury compared to females in the experiment. 3. Lower limb motor injury: combined IRR of 0.66 (95% CI2 0.56-0.77); Z = 5.12; P< 0.00001). The male group had a higher risk of loss compared to the female group in the experiment. 4. Knee movement injury: combined IRR of 0.73 (95% CI2 0.63-0.84); Z = 4.44; P< 0.00001). The female group had a higher risk of loss compared to the male group in the experiment. 5. Ankle sports injury: combined IRR of 0.54 (95% CI2 0.40-0.74); Z = 3.90; P< 0.00001). The male group had a higher risk of loss compared to females in the experiment. 6. Acute sports injury: The combined IRR is 0.60 (95% CI2 0.49-0.74); Z = 4.84; P< 0.00001), The male group had a similar reduced risk of loss compared to females in the experiment. 7. Chronic sports injury: The combined IRR was 0.72 (95% CI2 0.52-0.98; Z=2.07; P=0.04), and the female group had a higher risk of loss compared to males in the trial.

Conclusion: Neuromuscular training has significant effects in preventing upper and lower limbs, knees, ankles, and acute and chronic sports injuries of different genders. Research has shown that neuromuscular training has similar effects on different genders, effectively reducing the burden of public health and promoting participation in sports activities. However, more high-quality randomized controlled trials are still needed to further validate these findings.

Keywords: Neuromuscular training; injury care; sports rehabilitation; meta-analysis

1. Introduction

The rate of sports participation among adolescents is very high, significantly impacting th

eir health. It provides psychosocial benefits such increased selfas esteem, motor skill development, socialization, teamwork, competitiveness, and stress reducti on. However, sports are also a major cause of injury among adolescents, accounting for 30% [1of all adolescent injuries in many countries ^{4]}. Annually, 35% of adolescents injured in sports require medical rehabilitation, with lower e xtremity injuries being the most common, constituting over 60% of all youth sports injuries^{[5,} ^{6]}. Sports injuries can lead to decreased participation and are associated with allcause morbidity, overweight obesity, and or posttraumatic osteoarthritis ^[7, 8]. Hence, reducing the public health burden from youth sports injuri is of critical. The combination high es sportspecific participation rates and high injury rates results in adolescents producing the highest v olume of injuries in related sports, especially in team sports for both boys and girls. Boys exp erience the highest injury rates in ice hockey, rugby, basketball, soccer, wrestling, and runnin g. Girls face the highest injury rates in basketball, soccer, ice hockey, European handball, run [9, 10] hockey ning, and field Reducing injury in highrates burden sports can promote physical activity and significantly improve the quality of life.

Completely eliminating all injuries in adolescent sports is impossible, but adopting injury prevention strategies can reduce the number and severity of injuries. In recent years, an increa sing number of injury prevention programs have been developed. Among these, neuromuscula r training has been shown to positively impact adult injury rates ^[11-14]. A recent meta-analysis found that neuromuscular training for soccer can reduce injury rates by 20-50% ^[11]. Regarding ankle injuries, neuromuscular interventions and proprioception programs have been found to reduce the risk for physically active adults by 35-50% [12, 14]. Similar effects have been reported for adolescent athletes, with three meta-analyses showing a reduction in lower extremity injury risk by approximately 25-35% ^[15-17].

Although the preventative and therapeutic effects of neuromuscular training on adolescentsportsinjuriesarewell-established, little is known about its specific impact on gender, injury site, and type. Neuromuscular injury prevention programs for adolescent athletes have been studied across various spo

4

[21-[18-21] including basketball rts. soccer ^{26]}, and volleyball ^[26, 27]. In addition to specific sports content, these programs often include m ultiple components or focus on balance exercises [28, 29]. Common elements of multiintervention programs include strength, balance, flexibility, plyometric, speed, and agility trai ning, emphasizing neuromuscular control and proactive joint stability. Consequently, it is chal lenging to deduce methods for different genders or sportsspecific injury sites or types based on individual studies. From a practical perspective, a deepe r understanding of the specific effects of neuromuscular training on gender, injury site, and ty pe is crucial for tailoring training programs to specific populations, thereby increasing the con fidence of coaches and athletes in implementing these programs.

In summary, although neuromuscular training has been shown to have preventative effect s in adolescent athletes, existing literature does not provide consistent recommendations regar ding its impact on different genders, injury sites, and types. This understanding aids practition ers in designing tailored programs and enhances the compliance of coaches and athletes with t hese interventions ^[30, 31]. This is particularly important for young athletes, as differences in the ir maturation status can lead to significant individual variations in anthropometric and neurom uscular performance. Therefore, this study primarily reviews the aspects of different genders, injury sites, and injury types, revealing the effects and potential mechanisms of neuromuscula r training in preventing adolescent sports injuries. This provides critical insights for future pre vention and management of sports injuries in adolescents.

2. METHODS

We followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines^[32] in this systematic review. As this study was a review, no ethical approval was necessary. The methods and protocol registration were preregistered prior to conducting the review: INPLASY, no.2024110054, DOI:10.37766/inplasy2024.11.0054.

2.1 Data sources and search strategy

Two researchers independently searched PubMed, Web of Science, EBSCO, and Scopus databases for literature on using neuromuscular training to prevent lower limb sports injuries i

n adolescent athletes. The search scope included published clinical studies, with the search per iod extending from the establishment of each database to May 2024. The search languages we re English. The search terms combined subject terms and free terms. The search keywords inc luded: "Neuromuscular training, balance training, proprioceptive training, wobbleboard traini ng, athletic injuries, sport injury, injury, child, youth, team sport, injury prevention, interventi on, warm-up". The search strategy is detailed in Table 1.

Table 1 English Search Strategies

#5 #1 AND #2 AND #3 AND #4										

2.2 Selection Criteria

Based on the PICOS strategy, the following criteria had tobe fulfilled in order for studies to be considered in thismeta-analysis: (i) the study population consisted of youths of 21 years or younger, participating instructured/organized sport programs on a competitive level (P);(ii) a neuromuscular training program (including componentssuch as balance, agility, strength, neuromuscular control) wasevaluated with no co-interventions (e.g., education) provided(I); (iii) the study contained a control arm either performingusual practice routine or sham exercises without specific focuson neuromuscular control (C); (iv) any form of muscle, ligament, or bone injury in different genders, including acute or chronic injury data (O); (v)an analytical design was used (RCTs, quasi-experimental trials,cohort studies) (S). Studies without original data (review articles)or without obtainable data for meta-analysis were excluded.

2.3 Risk of Bias Assessment

We analyzed risk of bias of included studies using the PEDroscale. This scale consists of eleven items, addressing internal validity (8 items), interpretability (2 items), and external validity (1 item). A point was scored for each itemclearly fulfilling the criterion, allowing a maximal score of 11points. Two reviewers (SST, ALR) independently performed the quality rating. Disagreements between ratings were discussed and solved via consensus. This process

was piloted on threestudies not included in the review before actual quality rating wasperformed.

2.4 Data Extraction

Two researchers independently reviewed the titles and abstracts of the literature accordin g to the inclusion and exclusion criteria, excluding irrelevant studies. After reading the full tex ts, they further screened and identified the final included studies. Once literature screening wa s completed, two researchers independently extracted data, including: 1) general information s uch as the first author and publication date; 2) study design and groups; 3) sample size, gender, type of sport, and level; 4) intervention methods and duration; 5) outcome measures, includin g types and sites of injuries. In case of any discrepancies, decisions were made through discus sion with other research team members.

2.5 Statistical analyses

Statistical analyses were conducted using RevMan 5.4 and Stata 16.0 software. Multiple r esearchers verified data entry to ensure accuracy. The injury rate ratio (IRR) and correspondin g 95% confidence interval (CI) were calculated, representing the effect estimate for each inclu ded study. The IRR was determined as follows: IRR = (number of injuries in the NMT group / player exposure) / (number of injuries in the control group / player exposure). When player e xposure time was unavailable, the IRR was calculated based on the number of practice and ga me exposures. An IRR value less than 1 indicates a reduction in injury risk favoring neuromus cular training, with values closer to 0 showing greater effectiveness. Heterogeneity among the included studies was quantitatively analyzed using the I² statistic. When I² \leq 50%, a fixedeffects model was used: otherwise. randomа effects model was employed ^[33]. Sensitivity analyses tested the stability of the results, and sub group analyses by gender, injury site, and type explored the impact of study characteristics on outcome variables and sources of heterogeneity. Publication bias was assessed using Egger's t est.

3. Results

3.1 Trial Flow

A total of 544 studies were initially screened. After removing 333 duplicates and excludin g 264 studies based on their titles and abstracts, 69 studies were selected for full-text evaluation. Ultimately, 32 studies were included in the meta-analysis ^[27, 34-63], with a combined sample size of 34,581 participants.

The literature screening process is illustrated in Figure 1, and the basic information of the included studies is summarized in Table 2.

3.2 Methodological Quality

Among the included studies, 32 mentioned "randomization" or "randomized controlled trials" (RCTs). Twelve studies specified allocation concealment measures ^[34, 36, 38, 40, 41, 46, 48, 50, 52, 57, 62, 63], with one study using blinding for physical therapists^[57] and another for assessors^[35]. None of the studies exhibited selective reporting or incomplete data, nor did they mention other sources of bias. The proportion of bias risk and study results are presented in Figures 3 and 4. According to the PEDro scale, all 32 included studies were of high quality, scoring above 6. The overall quality of the included studies was high, with scores concentrated between 6 and 7. The PEDro scale scores are detailed in Table 3.

3.3 Meta-Analysis Results

3.3.1 Overall Effect of NMT

A total of 21 randomized controlled trials (RCTs) encompassing 4,375 sports injuries were included, resulting in a combined Incidence Rate Ratio (IRR) of 0.67 (95% CI 0.57-0.79; Z = 4.78; P < 0.00001), indicating a statistically significant 33% reduction in overall sports injury risk. There was significant

heterogeneity among gender subgroups ($I^2 = 74.0$; Q = 4.54; P = 0.1), suggesting differences in the combined effect estimates within subgroups (Figure 5). Trials involving male (IRR = 0.69; 95% CI 0.54-0.88) or mixed-gender participants (IRR = 0.57; 95% CI 0.43-0.76) showed a greater reduction in injury risk compared to those involving females (IRR = 0.84; 95% CI 0.69-1.02). To explore the source of heterogeneity, a sensitivity analysis was conducted by sequentially excluding each study included in the overall analysis to evaluate its impact on the IRR. The results indicated minimal heterogeneity among the studies, with the exclusion of any single study having a negligible impact on the IRR effect size. Thus, the results of the meta-analysis were relatively stable (Figure 6).

Figure 5 | Subgroup analysis of the IRR effect of gender on the overall injury effect of neuromuscular training

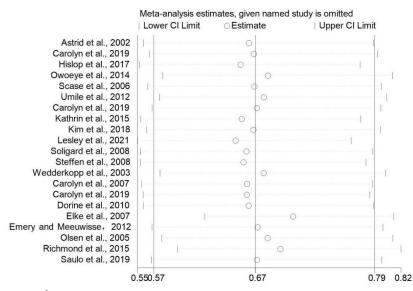

Figure 6 | Sensitivity analysis of overall damage effect

3.3.2 Effect of upper limb sports injury

A total of six RCTs involving 432 sports injuries were included, resulting in a combined Incidence Rate Ratio (IRR) of 0.73 (95% CI 0.59-0.9; Z = 3.12; P = 0.002), indicating a statistically significant 27% reduction in upper limb sports injury risk. Heterogeneity among gender subgroups was not significant (I^2 = 0; Q = 2.00; P = 0.37), suggesting no notable differences in combined effect estimates within subgroups (Figure 7). Trials involving male participants (IRR = 0.76; 95% CI 0.59-0.99) or mixed-gender groups (IRR = 0.73; 95% CI 0.59-0.89) showed a lower reduction in injury risk compared to those involving fe

Semale participants (IRR = 0.36 ; 95% CI 0.13 -1.00).

involving male participants (IRR = 0.97; 95% CI 0.34-2.80).

Figure 9 | Subgroup analysis of the impact of gender on the IRR of knee sports injuries

3.3.5 Effect of ankle sports injury

A total of 16 RCTs involving 496 sports injuries were included, resulting in a combined Incidence Rate Ratio (IRR) of 0.54 (95% CI 0.40-0.74; Z = 3.90; P < 0.00001), indicating a statistically significant 46% reduction in upper limb sports injury risk. Significant heterogeneity was observed among gender subgroups (I2 = 77.9; Q = 9.05; P = 0.01), suggesting notable differences in combined effect estimates within subgroups (Figure 10). Trials involving male participants (IRR = 0.32; 95% CI 0.16-0.67) or mixed-gender groups (IRR = 0.67; 95% CI 0.55-0.80) showed a greater reduction in injury risk compared to those involving female participants (IRR = 0.90; 95% CI 0.72-1.13). To explore the source of heterogeneity, a sensitivity analysis was conducted by sequentially excluding each study included in the overall analysis to evaluate its impact on the IRR. The results indicated minimal heterogeneity among the studies, with the exclusion of any single study having a negligible impact on the IRR effect size. Thus, the results of the meta-analysis were relatively stable (Figure 11).

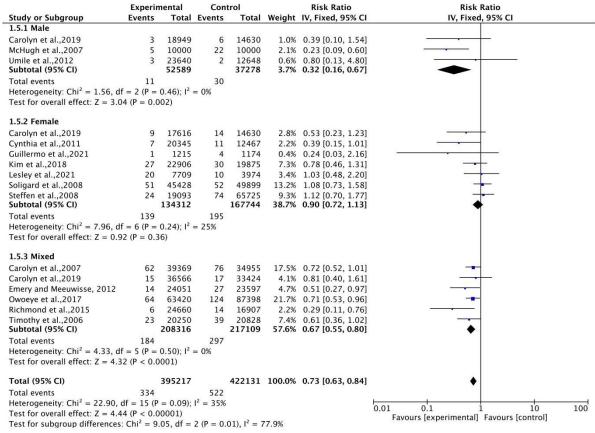

Figure 10 | Subgroup analysis of the impact of gender on the IRR of ankle sports injuries

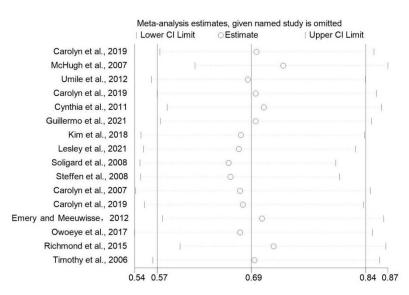

Figure 11 | Sensitivity analysis of aankle sports injuries

3.3.6 Effect of acute sports injury

A total of 13 randomized controlled trials (RCTs) involving 1,690 sports injuries were included, resulting in a combined Incidence Rate Ratio (IRR) of 0.60 (95% CI 0.49-0.74; Z = 4.84; P < 0.00001), indicating a statistically significant 40% reduction in upper limb sports injury risk. Heterogeneity among gender subgroups was not significant (I² = 0; Q = 0.07; P = 0.97), suggesting no notable differences in

combined effect estimates within subgroups (Figure 12). Trials involving male participants (IRR = 0.59; 95% CI 0.19-1.81), female participants (IRR = 0.62; 95% CI 0.43-0.88), and mixed-gender groups (IRR = 0.58; 95% CI 0.45-0.75) showed similar reductions in injury risk. To explore the source of heterogeneity, a sensitivity analysis was conducted by sequentially excluding each study included in the overall analysis to evaluate its impact on the IRR. The results indicated minimal heterogeneity among the studies, with the exclusion of any single study having a negligible impact on the IRR effect size. Thus, the results of the meta-analysis were relatively stable (Figure 13).

Figure 12 | Subgroup analysis of the impact of gender on the IRR of acute sports injuries

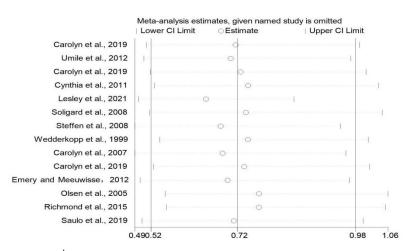

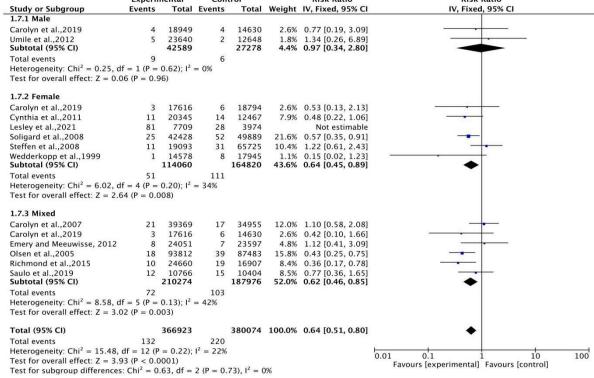

Figure 13 | Sensitivity analysis of acute sports injuries

3.3.7 Effect of chronic sports injury

A total of 14 RCTs involving 461 sports injuries were included, resulting in a combined Incidence Rate Ratio (IRR) of 0.72 (95% CI 0.52-0.98; Z = 2.07; P = 0.04), indicating a statistically significant 28% reduction in upper limb sports injury risk. Heterogeneity among gender subgroups was not significant (I² = 0; Q = 0.65; P = 0.72), suggesting no notable differences in combined effect estimates within subgroups (see Figure 14). Trials involving female participants (IRR = 0.75; 95% CI 0.44-1.28) or mixed-gender groups (IRR = 0.63; 95% CI 0.42-0.98) showed a greater reduction in injury risk compared to those involving male participants (IRR = 0.97; 95% CI 0.34-2.80).

3.4 Risk of Publication Bias Assessment

Using the Egger's test to evaluate publication bias in the included studies, the results are shown in Table 3. The P-values for overall injuries (P=0.405), upper limb injuries (P=0.419), lower limb injuries (P=0.494), knee injuries (P=0.582), and chronic injuries (P=0.307) are all greater than 0.05, indicating no significant publication bias in the included studies for these outcome indicators, and the results are relatively stable. However, the P-values for ankle injuries (P=0.034) and acute injuries (P=0.022) are less

than 0.05, indicating significant publication bias.

4. Discussion

In the early stages of training, adolescents should engage in a variety of sports and movement patterns, gradually increasing training intensity as they age and adapt physiologically to develop comprehensive physical capabilities. Initially, they should learn basic movement techniques and train their physical abilities, transitioning these abilities to specialized sports techniques to optimize athletic performance. Literature suggests that diverse training helps build the physical foundation of young athletes, serving as the basis for specialized sports skills and reducing the risk of sports injuries. Neuromuscular adaptation is a crucial factor in the progress of children's and adolescents' athletic performance, so training during this period should emphasize neuromuscular stimuli. NMT, which incorporates various physical elements such as strength, explosiveness, speed, agility, and balance, is often used as a warm-up before specialized training or as an independent training session. Additionally, practicing the basic techniques of various physical elements in NMT promotes athletic performance and prevents sports injuries. One notable and effective NMT program is the injury prevention initiative (FIFA 11+ Kids) developed by the International Federation of Association Football (FIFA), combining core stability, eccentric strength, balance, plyometrics, and fall techniques to prevent injuries and enhance performance.

The primary objective of this meta-analysis is to determine the efficacy of NMT in different genders,

body parts, and injury types to develop more targeted training methods to reduce the risk of sports injuries in adolescents. Overall, consistent with previous research, the included studies show that NMT significantly prevents injuries (IRR 0.67, 95% CI 0.57-0.79), reducing injury risk by 33%. Subgroup analysis reveals that the reduction in sports injury risk is more pronounced in male and mixed-gender groups, with effect sizes within these groups all less than 1. In contrast, two studies in the female group indicate that NMT is ineffective in preventing sports injuries. In Steffen et al.'s study, the compliance rate of coaches and players was only 52%, which might explain the non-significant results. Differences in attitudes and beliefs about the importance of injury prevention training and injury prevention among youth sports coaches and adolescents may exist^[74-78]. The study suggests that coaches who undergo methods such as coaching workshops to learn preventive programs are more likely to effectively implement prevention plans based on a correct understanding of the techniques. Given the lack of injury prevention training and medical follow-up resources for adolescents, it is crucial to make injury prevention a mandatory part of coach education certification at all levels.

In young female football, basketball, and gymnastics athletes, the ankle, knee, and thigh are the most common injury sites. Another study indicates that the ankle and knee are the most common injury sites in young females, further supporting the need for lower limb injury prevention programs in young females. In subgroup analyses by site and gender, almost all groups show that NMT significantly prevents injuries and greatly reduces injury risk. However, we found no significant differences in the prevention of male knee injuries (P=0.96) and female ankle injuries (P=0.36). The limited number of studies reporting male knee injury outcomes (only two) may affect the results, highlighting the need for further studies. In the studies included for female ankle injuries, three studies reported IRR effect sizes greater than 1. In Steffen and Soligard et al.'s studies, issues with low compliance among coaches and adolescents during training might contribute to the ineffectiveness of NMT in reducing injury probability. Finally, in studies on injury types, NMT significantly prevents both acute and chronic injuries.

Despite the increasing number of studies providing effective methods for preventing adolescent sports injuries, there is still a lack of learning, absorption, and continued use of these methods after systematic evaluation. This highlights the need to focus on the implementation context and real-world effectiveness when evaluating adolescent sports injury prevention programs^[82-84]. In team sports like football, these programs must be customized for specific sports, particularly emphasizing coach training to ensure

effective implementation. It is also important to propose a tiered responsibility system, assigning the lowest responsibility to adolescents and the highest responsibility to organizations or groups that can have the most significant impact. This approach is based on the rationale that simply relying on behavior changes from adolescents and parents and the cognitive development level of adolescents to demonstrate the program's effectiveness is insufficient, as their level is inadequate to bear primary responsibility for their safety in sports. Additionally, more attention should be paid to implementation-related research, including fundamental behavior changes in the adolescent athletic population and the key role of coaches in injury prevention, which is critical for knowledge dissemination, behavior change, and sustainable injury prevention practices and policies.

In conclusion, NMT can prevent the occurrence of sports injuries in adolescents. Given the issues of limited studies in certain subgroups and low methodological quality in this meta-analysis, large-sample, high-quality clinical randomized controlled trials are still needed to further explore the impact of NMT on sports injuries of different genders, sites, and types. Overall, NMT is an effective and safe intervention that can be implemented before specialized training or as an independent training session to prevent sports injuries in adolescents.

5. Limitations

Some of the included studies had low quality and did not specify the implementation of allocation concealment and blinding. Significant heterogeneity existed among the included studies, affecting the reliability of the results. The intervention frequency, duration, and intensity varied among the studies, introducing potential bias. The participants exhibited diversity in sports type and level, ranging from amateur to high school and professional. Soomro et al.^[87] and Rössler et al.^[88] noted that studies involving amateurs showed a more significant risk reduction compared to those targeting professional-level adolescents. Body weight and prior injury history also play crucial roles in sports injuries. Therefore, the heterogeneity observed in the meta-analysis may not only be due to differences in the content and dosage of neuromuscular training programs but also the specific characteristics of the study populations. Adherence is a key factor in evaluating the effectiveness of injury prevention programs^[89, 90]. Coach-reported adherence may be overestimated since most coaches did not use all prescribed exercises, and several studies failed to collect adherence data from coaches and adolescents, thus not included in the analysis. Future research

should focus on large-scale, high-quality randomized controlled trials to further investigate the effects of neuromuscular training on preventing sports injuries in different populations and intervention methods.

6. Conclusion

This paper analyzes recent advancements in the application of NMT for preventing sports injuries among adolescents, initially describing its positive effects. Studies indicate that NMT effectively prevents upper and lower limb, knee, ankle, as well as acute and chronic sports injuries across different genders, with similar efficacy. This training ensures safety during sports, improves physical and mental health, reduces public health burdens, and promotes participation in physical activities. However, the effectiveness of NMT is influenced by factors such as age, body weight, sports level, injury history, and training content design. Therefore, future research should develop more refined NMT programs tailored to different types of participants, providing more evidence for clinical practice to achieve optimal prevention outcomes.
