Abstract. When using the unique in terms of the volumes of database on the level of a stand of the genus *Larix* Mill., the trans-Eurasian additive allometric models of biomass for Eurasian larch forests are developed for the first time, and thereby the combined problem of model additivity and generality is solved. The additive model of forest biomass of *Larix* is harmonized in two levels, one of which provides the principle of additivity of biomass components, and the second one is associated with the introduction of dummy independent variables localizing model for eco-regions of Eurasia. Comparative analysis of the biomass structure of larch stands of different ecoregions at the age of 100 years shows, that the greatest values of biomass (210-450 t/ha) correspond to the regions adjacent to the Atlantic and Pacific coasts, as well as to the regions, located at the southern limit of larch growing area and the lowest – to northern taiga regions of Siberia, where larch grows on permafrost. The biomass indices of different ecoregions differed not only in absolute value but also in biomass ratios of different components; for example, the proportion of needles in the aboveground biomass is maximum (5.0-7.3%) in the northern taiga of Central Siberia and the Far East on permafrost and is minimum (1.4-1.9%) in larch forests of upper productivity having biomass values 210-450 t/ha. The proposed model and corresponding tables for estimating stand biomass makes them possible to calculate larch stand biomass on Eurasian forests when using measuring taxation.

Keywords: allometric models, biological productivity, biomass of forests; *Larix* Mill., sample plots.

1. Introduction

Evaluation of biological productivity and carbon-depositing ability of forests is currently one of the priority directions of forest ecology in relation to global climate change. In recent years, scientific direction associated with the evaluation of the biological productivity of trees and stands, is the most intensely developed in at least two aspects: (1) in compiling the world's data bases on actual biological productivity at the levels of forest stands and single-trees with development of their global and transcontinental pat-

terns (Gill & Jackson, 2000; Usoltsev et al., 2002; Schenk & Jackson 2002, 2003; Crowther et al., 2015; Poorter et al., 2015; Liang et al., 2016; Jucker et al., 2017) and (2) in the development of methodological backgrounds of regression modeling with the aim to improve the accuracy of our estimates and the correctness of the empirical models of biological productivity of forests and their constituent trees (Parresol, 2001; Usoltsev et al., 2002; Dong et al., 2015a, b).

Generic allometric models were intensively developed only on aboveground biomass, they seemed promising for estimating forest biomass in total, usually within the single wood species (Tritton & Hornbeck, 1981; Schmitt & Grigal, 1981; Crow, 1983; Pastor et al., 1984; Grigal

* corresponding author.

& Kernik, 1984; Zianis & Mencuccini, 2003; Case & Hall 2008; De-Miguel et al., 2014), and in tropical forests also within the totality of different species (pan-tropical models) (Ogawa et al., 1965; Crow, 1978; Chave et al., 2005, 2014; Vieilledent et al., 2012; Rutishauser et al., 2013; Stas et al., 2017).

But because various biomass components are characterized by different rates as growth and mortality, they make a different contribution to the cycling of substances and should be evaluated separately. Therefore, the development of generic allometric models is replaced by a phasing out of them and moving on to the concept of their harmonizing. To the latter at least two directions can be attributed: (1) construction of compatible regional models based on dummy variables (Usoltsev et al., 2002; Dieguez-Aranda et al., 2006; Nord-Larsen, 2006; Li et al., 2006; Wang et al., 2007, 2008; Fehrmann et al., 2008; Lang, 2008; Tang et al., 2008; Li & Zhang, 2010; Zeng et al., 2011; Fu et al., 2012, 2013, 2017; Zeng, 2015) and (2) the development of compatible models based on principles of additivity of biomass component composition (Parresol, 2001; Carvalho & Parresol, 2003; Bi et al., 2004, 2015; Sanquette et al., 2015; Dong et al., 2015a, b; Dong et al., 2016). Additive allometric models are designed today exclusively at the level of single trees. Similar models developed at the level of forest stands, to which is dedicated this work, are presented today with single researches, that are fulfilled, for example, in *Pinus radiata* (D. Don) plantations (Bi et al., 2010) and in mixed spruce-fir forests of Eurasia (Usoltsev et al., 2017a, b), and models were built using alternative algorithms of harmonization that are defined respectively as «from private-to-general» (Bi et al., 2010) and «from general-to-private» (Usoltsev et al., 2017a, b) without attempting any of their regionalization.

Thus, the modern methods of modelling the biological productivity of trees and tree stands have been developed towards additivity of biomass components (Bi et al., 2010; Dong et al., 2015b) and towards transition from «pseudo-generic» allometric models to really generic, involving regionalization of biomass models by introducing dummy variables (Fu et al., 2012), that usually fulfilled on local sets of actual biomass of trees and tree stands. We generated the database of forest stand biomass for the main forest species in Eurasia (Usoltsev, 2010, 2013), that has enabled these modern methodologies to be implemented on the entirely different, higher level, namely to begin modelling additive biomass on transcontinental level.

So far, the additivity principle is implemented only for local models of forest stand biomass (Bi et al., 2010). Its complexity and structural unwieldiness of analytical expression, apparently, are the reason that nowadays it is not implemented at the continental level, for example, by

the dismemberment of a general additive biomass model on a set of compatible regional sub-models, marked by dummy variables or in some other way. Previously (Usoltsev et al., 2017a, b) the transcontinental additive biomass models of forest stands of Norway spruce (*Picea* Dietr.) and fir (*Abies* Mill.) growing on the territory of Eurasia were first proposed, that are generic additive models for these species i.e. without taking into account their regional specificities.

In this article, the first attempt to develop transcontinental harmonized allometric models of larch (genus *Larix* Mill.) forest stand biomass, which combine both mentioned by Jacobs and Cunia (1980) approaches, namely, ensuring the principle of additivity of biomass component composition and localizing (dismemberment) of biomass additive model on regions of Eurasia by introducing dummy variables. In other words, an attempt is made to solve the problems of combining additivity and totality of models. These models will provide the basis for the development of trans-continental regional standards for evaluation biomass of trees and forest stands.

2. Material and methods

Of the database mentioned the material in a number of 384 sample plots with estimations of larch forest stand biomass (t/ha) is extracted. Genus *Larix* Mill. is introduced by eight species (correspondingly *L. decidua* Mill., *L. sukaczewii* N.Dyl., *L. sibirica* L., *L. gmelinii* Rupr., *L. cajanderi* Mayr., *L. olgensis* A.Henry, *L. principis-rupprechtii* Mayr, *L. leptolepis* Gord.; taxonomy according to Sokolov et al., 1977, and Bobrov, 1978), distributed across twelve eco-regions and designated respectively with the twelve dummy variables from X_0 to X_{11} (Table 1). The distribution of sample plots, on which the larch forest biomass is measured in ecoregions of Eurasia, is shown in Figure 1.

According to the structure of disaggregation three-step model (Tang et al., 2000; Dong et al., 2015b), biomass value, estimated by the total biomass equation, exploded into components according to the scheme presented in Figure 2. The coefficients of the regression models for all three steps are evaluated simultaneously, which ensures additivity of biomass of all the components – total, intermediate and initial (Dong et al., 2015b).

Figure 1. Allocation of sample plots with measured biomass (t/ha) of 384 stands of larch (genus *Larix* Mill.) on the territory of Eurasia

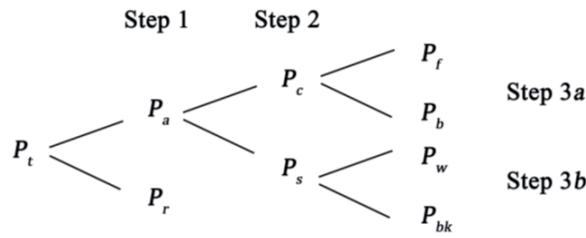

Figure 2. The pattern of disaggregating three-step proportional weighting additive model. Designation: P_t , P_r , P_a , P_c , P_s , P_f , P_b , P_w and P_{bk} are stand biomass respectively: total, underground (roots), aboveground, crown (needles and branches), stems above bark (wood and bark), needles, branches, stem wood and stem bark correspondingly, t per ha

3. Results and discussion

The initial allometric models are calculated;

$$\ln P_i = a_i + b_i (\ln A) + c_i (\ln A)^2 + d_i (\ln H) + e_i (\ln D) + f_i (\ln N) + \sum g_{ij} X_j \quad (1)$$

where P_i – biomass of i -th component, t per ha; A – stand age, years; H – mean stand height, m; D – mean tree diameter, cm; N – tree number, 1000/ha; $a-g$ – regression coefficients; i – index of biomass component: total (t), aboveground (a), roots (r), crowns (c), stems above bark (s), needles (f), branches (b), stem wood (w) and stem bark (bk); j – index (code) in the block of dummy variables coding the ecoregions, from 0 to 11 (see Table 1).

Model (1) after anti-log transformation is given to the form

$$P_i = a_i A^{b_i} A^{c_i(\ln A)} H^{d_i} D^{e_i} N^{f_i} e^{\sum g_{ij} X_j} \quad (2)$$

Characteristic of equations (1) obtained by its approximation using actual biomass data, after the introduction of correction to the logarithmic transformation after Baskerville (1972) and the subsequent anti-log transformation to (2) are given in the Table 2. All the regression coefficients of the equations (2) with numerical variables are significant at the level of probability of 0.95 or higher, and the equations are adequate to actual data.

The equations (2) are modified according to the algorithm proposed by Chinese researchers (Dong et al., 2015b) (Table 3), and the final transcontinental additive model of larch biomass component composition on the level of forest stand is given in the Table 4. The model is valid in the range of actual data of stand age, mean tree height, mean stem diameter and tree density, listed in the Table 1, and is characterized by a double harmonization: one of which provides the principle of biomass component

additivity, and the second one relates to the introduction of dummy variables, localizing the model according to ecoregions of Eurasia.

At the next stage of the study a comparison of the adequacy of additive model (see Table 4) and independent equations shown in the Table 2. For their correct comparing the sample plots with incomplete biomass component structure are deleted from the initial harvest data, i.e. only those records are left in which the data are available on both aboveground and underground biomass. The equations (2) are approximated according to such “methodized” data, and their final forms are given in the Table 5. As the “methodized” additive model, and “methodized” independent equations, are tabulated according to actual mass-forming indices of the modified data and the obtained values are compared with harvest biomass data using the formula:

$$R^2 = 1 - \frac{\sum_{i=1}^N (Y_i - \bar{Y}_i)^2}{\sum_{i=1}^N (Y_i - \bar{Y})^2}, \quad (3)$$

where Y_i is observed value; \hat{Y}_i is predicted value; \bar{Y} is the mean of N observed values for the same component.

The results of comparison of the adequacy of two modeling methods are summarized in the Table 6 and they indicate that the adequacy of the two systems of equations for aboveground biomass, underground one and stem biomass are similar and the indices of additive equations for mass of crown, needles and branches are slightly worse. This corresponds to the view (Cunia & Briggs, 1984; Reed & Green, 1985), that the correction of internal inconsistency of biomass equations by ensuring their additivity does not necessarily means improvements in the accuracy of biomass estimating.

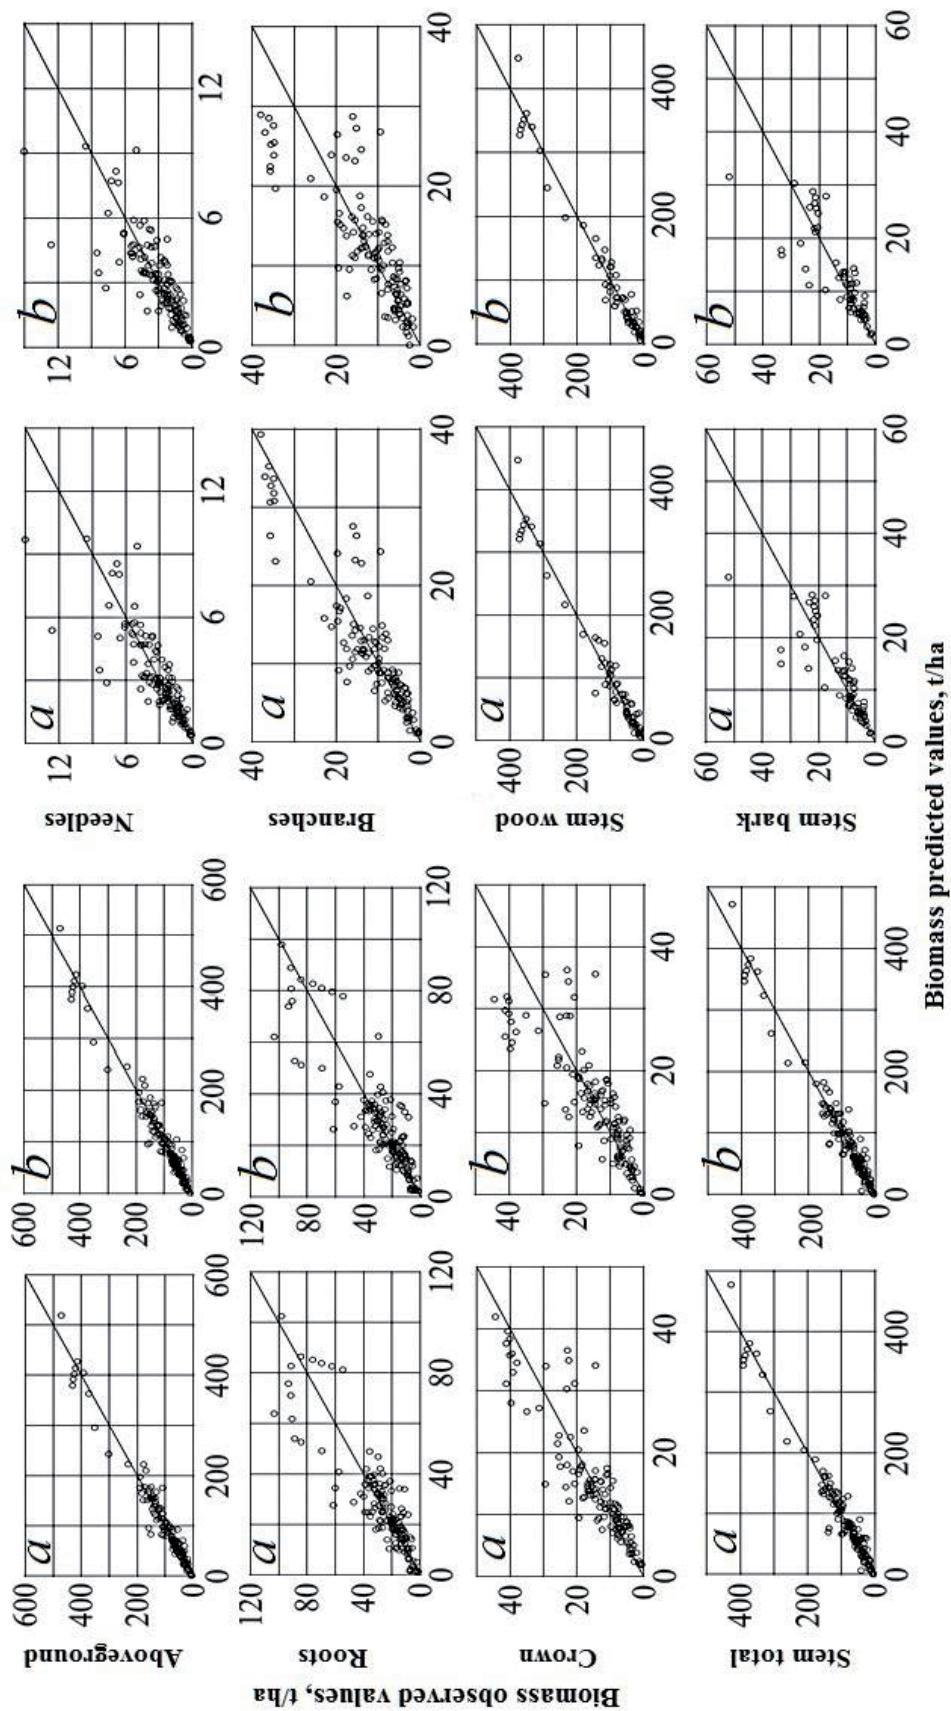

Figure 3. The ratio of observed values and the values derived by calculation of independent (a) and additive (b) models of stand biomass

The ratio of actual values and derived ones by tabulating independent and additive stand biomass models (Fig. 3) shows the degree of correlativeness of the actual and calculated values and, in many cases, the absence of visible differences in the structure of residual variances obtained on two named models. More or less the value of R^2 of one or the other model is determined by the random position of actual values of maximum stand biomass in confidence range and uneven dispersion, namely accidental because of their small number and the greatest contribution to the residual variance (see Fig. 3).

The additive model built (Table 4) includes four numeric independent variables. When its tabulating, there is a problem, which is that we can know and give the value of stand age only of four variables, and the remaining three variables can be entered into the table in the form of calculated values obtained by the system of auxiliary recursive equations (Usoltsev et al., 2017b). Such equations are approximated using the original data and are shown in the Table 7.

The results of sequential tabulations of the equations of the Table 7 and 4 give the unacceptably voluminous table, the size of which exceeds the format of journal article. Therefore, a comparative analysis of the biomass structure of larch stands of different ecoregions we limit by the stand age of 100 years (Table 8). According to the table. 8, the greatest values of biomass (210-450 t/ha) correspond to the regions adjacent to the Atlantic and Pacific coasts, as

well as to the regions, located at the southern limit of larch growing area and the lowest – to northern taiga regions of Siberia, where larch grows on permafrost. The biomass indices of different ecoregions differed not only in absolute value but also in biomass ratios of different components; for example, the proportion of needles in the aboveground biomass is maximum (5.0-7.3%) in the northern taiga of Central Siberia and the Far East on permafrost and is minimum (1.4-1.9%) in larch forests of upper productivity having biomass values 210-450 t/ha.

4. Conclusion

When using the unique in terms of the volumes of database on the level of a stand of the genus *Larix* Mill., the trans-Eurasian additive allometric models of biomass for Eurasian larch forests are developed for the first time, and thereby the combined problem of model additivity and generality is solved. The additive model of forest biomass of *Larix* is harmonized in two levels, one of which provides the principle of additivity of biomass components, and the second one is associated with the introduction of dummy independent variables localizing model for ecoregions of Eurasia. The proposed model and corresponding tables for estimating stand biomass makes them possible to calculate larch stand biomass on Eurasian forests when using measuring taxation.
